(54) **Non-contacting position detecting apparatus.**

(57) A non-contacting position detecting apparatus includes a laser unit (10) having a light emitting portion (12) and a light receiving portion (15) for irradiating laser light (L0) upon a detection point (100) of a subject for measurement and receiving laser light (L1) reflected from the detection point (100) to recognize the distance to the detection point. An arm is capable of moving the laser unit (10) in the direction of at least one axis of a rectangular coordinate system. A coordinate detecting member is provided for detecting coordinates of the arm. Coordinates of the detection point (100) are recognized in accordance with the coordinates of the arm when the positional relationship between the detection point (100) and the laser unit (10) reaches a predetermined relationship. The laser unit (10) includes a needle-like indicating member (30) for indicating the crossing point between extension lines of an optic axis of laser light (L0) radiated from the light emitting portion (12) and an optic axis of laser light (L1) received by the light receiving portion (15) when the detection point (100) and the laser unit (10) reach the predetermined positional relationship.

EP 0 565 357 A2

The present invention relates to a non-contacting position detecting apparatus, and particularly to a non-contacting position detecting apparatus suitable for use with a non-contacting three-dimensional measuring instrument which can perform a reliable and accurate measurement of coordinates of various portions of an outer profile of a subject to be measured.

Three-dimensional measuring instruments which detect a three-dimensional shape as three-dimensional coordinate data are disclosed, for example, in U.S. Patents No. 3,722,842, No. 4,102,051, No. 4,149,317 and No. 4,282,654.

The three-dimensional measuring instruments include a body (arm) movable in the directions of axes of coordinates of a spatial rectangular coordinate system, that is, X, Y and Z axes which are perpendicular to each other, and a needle provided on the movable body. The needle contacts with a detection point of an outer profile of a subject for measurement to detect three-dimensional coordinates of the movable body upon such contacting to measure a three-dimensional profile.

However, with such contacting three-dimensional measuring instruments, where the subject for measurement is molded from a soft material such as, for example, clay, when an end of the needle is contacted with the detection point of the subject for measurement, the end is liable to bite into the subject for measurement so that an error is produced in detected coordinates of the subject for measurement. There is the possibility that concave and convex measurements may be produced on the outer profile of the subject for measurement.

In order to eliminate such a disadvantage, the three-dimensional measuring instrument should be of the non-contacting type wherein, for example, a laser light source and a light receiving element for receiving a reflected laser beam are used, the distance between the subject for measurement and the laser light source is measured and, at a point in time when the distance reaches a predetermined value, coordinates of the detection point of the subject for measurement are measured.

With a contacting three-dimensional measuring instrument, when the needle is directed perpendicularly to a predetermined position of the surface of a subject for measurement, coordinates of the position can be detected accurately. Accordingly, in such a non-contacting three-dimensional measuring instrument as described above, detection of coordinates is performed using such a customary technique.

The technique of detection of coordinates described above is described with reference to Figures 7(a) and 7(b). Referring to Figures 7(a) and 7(b), the Y-axis is disposed in a direction perpendicular to the plane of the figure. A subject for measurement 100 is provided adjacent a laser unit 10 having a laser light

source and a light receiving element for a laser beam disposed therein for detecting the distance to the subject 100 for measurement in a non-contacting condition.

The structure of the laser unit 10 is shown in Figure 12. Laser light radiated from a semiconductor laser 12, which is a light emitting element, is irradiated upon the subject 100 for measurement. When the subject 100 for measurement is disposed at a reference point Lref (for example, at the distance of 50 mm in the laser light irradiation direction from the laser light irradiation position of the laser unit 10), laser light reflected at random from a detection point of the subject 100 for measurement is received at a central position of a light receiving element 15. Further, when the position of the subject 100 for measurement is nearer (100A) or farther (100B) than the reference point, Lref, the light receiving position of laser light on the light position detecting element 15 moves in the direction of an arrow mark A or B. The output of the light position detecting element 15 is outputted to a first signal processing circuit 50, as illustrated in Figure 6.

When measurement is performed using such a laser unit 10, as shown in Figure 7(a), the mounting position of the laser unit 10 is set so that laser light 10A irradiated from the laser unit 10 is irradiated substantially perpendicularly upon a portion (detection point) of the subject 100 for measurement whose coordinates are to be detected, and thereafter, the laser unit 10 is fed in the X and Z directions simultaneously so that the laser unit 10 may move in the irradiation direction (the direction of an arrow mark L) of the laser light. When the laser unit 10 is moved closer to the subject 100 for measurement as shown in Figure 7(b), laser light 10B reflected from the subject 100 for measurement is detected by way of a lens system. When the light detected from a result of the detection that the laser unit 10 comes to a predetermined distance from the laser unit 10, coordinate data of the laser unit 10 or of an arm (not shown) which supports the laser unit 10 thereon are then collected as coordinate data corresponding to the laser light irradiation position (detection point) of the subject 100 for measurement.

As illustrated in Figures 19(a) to 19(c), a light emitting portion 101A and a light receiving portion 101B are provided for the laser light. As shown in Figure 19(a), the mounting position of the laser unit 101 is set so that laser light irradiated from the light emitting portion 101A of the laser unit 101 is irradiated substantially perpendicularly upon a portion of the subject 100 wherein the coordinates are to be measured. Thereafter, the laser unit 101 is fed in the X and Z directions simultaneously so that the laser unit 101 may move in the irradiation direction (the direction of an arrow mark L) of the laser light. When the laser unit 101 is moved closer to the subject 100 for measurement as shown in Figure 19(b), laser light reflected

from the subject 100 for measurement is detected by way of a lens system provided at the light receiving portion 101B. When the light is detected from a result of the detection that the laser unit 101 has arrived at a predetermined distance from the laser unit 101, coordinate data of the laser unit 101 or of an arm (not shown) which supports the laser unit 101 thereon is collected as coordinate data corresponding to the laser light irradiation position of the subject 100 for measurement.

With the non-contacting three-dimensional measuring instrument of the construction described above, since it does not include means for indicating such a desired detection point as corresponds to a needle of a contacting three-dimensional measuring instrument, it is difficult to designate a desired detection point rapidly and accurately. Accordingly, when it is tried to continuously measure a plurality of detection points on a curved line of a subject for measurement which has, for example, a curved profile, there is a problem that the operability is very inferior compared with that of a contacting three-dimensional measuring instrument.

It is an object of the present invention to make it possible to designate a desired detection point rapidly and accurately with a non-contacting position detecting apparatus solving the problems of the prior art described above.

In order to attain the object of the present invention, a non-contacting position detecting apparatus which includes a laser unit having a light emitting portion and a light receiving portion for irradiating laser light upon a detection point of a subject for measurement and receiving laser light reflected from the detection point to recognize the distance to the detection point is characterized in that the laser unit includes needle-like indicating means for indicating the crossing point between extension lines of an optic axis of the laser light radiated from the light emitting portion and an optic axis of laser light received by the light receiving portion when the detection point and the laser unit reach the predetermined positional relationship.

Since the needle-like indicating means described above is provided on the laser unit, if the laser unit is moved so that the needle-like indicating means may indicate a detection point, then the positional relationship between the detection point and the laser unit comes to the predetermined relationship, and accordingly, the desired detection point can be designated rapidly and accurately.

In a system wherein the irradiation direction L of laser light is directed perpendicularly to a predetermined surface of an outer profile of a subject for measurement and a laser unit is moved in the irradiation direction as described above, the laser unit 101 must necessarily be moved in the directions of two axes (the X-axis and the Z-axis in the example of Fig-

ures 19(a) to 19(c)) or in the directions of three axes simultaneously. In short, in order to move the laser unit 101 from the condition of Figure 19(a) to the condition of Figure 19(b), the laser unit 101 must necessarily be fed by  $x_f$  in the X direction and by  $z_f$  in the Z direction simultaneously as shown in Figure 19(c). Such simultaneous feeding of the laser unit 101 in the directions of a plurality of axes not only makes the mechanism much more complicated but also reduces the operability.

Meanwhile, in a method wherein the simultaneous feeding described above is performed separately (for example, feeding by  $x_f$  in the X direction is performed first, and then, feeding by  $z_f$  in the Z direction is performed) or another method wherein feeding in the X direction and feeding in the Z direction are performed alternately little by little. There is the possibility that, at the point in time when the laser unit 101 comes to a predetermined distance to the subject 100 for measurement (that is, at a point in time when coordinates are detected) the irradiation position of laser light may be a different position from an aimed position to be detected. In this instance, coordinates of the aimed position cannot be detected. It is an object of the present invention to provide a non-contacting three-dimensional measuring instrument which can readily effect detection of coordinates of a desired (aimed) position of a subject for measurement.

In order to solve the problems described above, a non-contacting three-dimensional measuring instrument is constructed using a main shaft provided on an arm of a layout machine such that the direction of the center axis thereof extends in the direction of one of axes of the coordinates of a spatial rectangular coordinate system, a first intermediate arm provided for pivotal motion on the main shaft, an auxiliary shaft provided on the first intermediate arm at an angle of 45 degrees with respect to the main shaft, a second intermediate arm provided for pivotal motion on the auxiliary shaft, and laser unit mounting means for mounting the laser unit on the second intermediate arm such that the direction of laser light irradiated from the laser unit makes an angle of 45 degrees with respect to the auxiliary shaft.

The non-contacting three-dimensional measuring instrument may include a laser unit mounting means constructed such that a point (hereinafter referred to as "reference point") at a predetermined distance in the laser light irradiation direction from the laser unit, which is positioned for making a reference for collecting coordinates, may be positioned at the crossing point between the main shaft and the auxiliary shaft.

The non-contacting three-dimensional measuring instrument may include a laser unit constructed so as to provide an irradiated laser light from a position other than a central portion thereof, the laser unit mounting means being constructed such that it can

mount the laser unit reversely with regard to the front and rear sides.

The non-contacting three-dimensional measuring instrument may include a first intermediate arm having a core member made of an epoxy honeycomb, a pair of bearings disposed at the opposite ends of the core member and carbon fibers wound on the surfaces of the core member and the bearings.

With the non-contacting three-dimensional measuring instrument according to a preferred embodiment the laser light irradiation direction can be directed to all of the directions of the three axes constituting the coordinate system by adjusting the pivoting angle of the first intermediate arm with respect to the main shaft and the pivoting angle of the second intermediate arm with respect to the auxiliary shaft.

With the non-contacting three-dimensional measuring instrument according to a preferred embodiment, if the position of the arm of the layout machine does not vary, the coordinates of the reference point are not varied even if the first intermediate arm and/or the second intermediate arm are pivoted to vary the irradiation direction of laser light.

With the non-contacting three-dimensional measuring instrument according to a preferred embodiment, if the laser unit is mounted reversely with the front side positioned on the rear side, measurement of coordinates can be performed in the proximity of a wall face of a recessed portion of the surface of the subject for measurement.

With the non-contacting three-dimensional measuring instrument according to a preferred embodiment, the first intermediate arm can be constructed light and firmly.

Further scope of applicability of the present invention will become apparent from the detailed description given hereinafter. However, it should be understood that the detailed description and specific examples, while indicating preferred embodiments of the invention, are given by way of illustration only, since various changes and modifications within the scope of the invention will become apparent to those skilled in the art from this detailed description.

The present invention will become more fully understood from the detailed description given hereinbelow and the accompanying drawings which are given by way of illustration only, and thus are not limitative of the present invention, and wherein:

 Figure 1 illustrates the construction of a principal portion of a laser unit 10 to which the present invention is applied. A needle-like indicating means 300 is provided for indicating a desired detection point on a subject 100 for measurement.

Figure 2(a) is an enlarged view showing the construction of the needle-like indicating means 300 in

detail, and Figure 2(b) is a sectional view taken along line 2-2 of Figure 2(a). The needle-like indicating means 300 includes a base plate 303 securely mounted, for example, on the laser unit 10, a supporting portion 301 having a tapping hole 301a, and a needle 302 screwed at a rear end portion thereof in the tapping hole 301a of the supporting portion 301 and having an end portion of a tapered profile.

The base plate 303 and the supporting portion 301 are secured to each other by a weak restraining force so that, when the needle 302 collides with the subject 100 for measurement, they may be spaced away from each other readily to prevent damage to the subject 100. The securing by such a weak restraining force can be achieved, for example, by a magnetic force such as a magnet MG. As illustrated in Figures 2 and 4, the end tip 302a of the needle 302 is pointed.

The needle 302 is transparent, and, as shown in Fig. 4, an end portion is roughened so that laser light is randomly reflected from it.

Figure 6 illustrates a noncontacting three-dimensional measuring instrument provided with the laser unit 10 described above, and like reference characters to those described above denote like or equivalent portions. In the following, the present invention will be described by applying the invention to the non-contacting three-dimensional measuring instrument, but the present invention is not limited to this and can be applied similarly to a one-dimensional measuring instrument for measuring the length of a subject 100 for measurement in a one-dimensional direction in a non-contacting condition or a two-dimensional measuring instrument for measuring the lengths in two-dimensional directions in a noncontacting condition.

Referring to Figure 6, a layout machine 1 is installed on a surface plate 200, and a guide rail 2 thereof is secured to the surface plate 200. A base plate 3 of the layout machine 1 is slidably movable in the Y direction along the guide rail 2, and a sliding frame 5 is slidably movable in the Z direction along a vertical arm 4 supported vertically on the base plate 3. Further, a horizontal arm 6 is slidably movable in the X direction along the sliding frame 5.

A laser unit 10 is mounted at an end of the horizontal arm 6 by way of an intermediate arm (first intermediate arm) 30 and a wing arm (second intermediate arm) 20. The mounting of the wing arm 20 and the laser unit 10 may be, for example, by screwing.

Accordingly, the laser unit 10 is movable to a suitable location within a three-dimensional spacing above the surface plate 200 by sliding movements of the base plate 3, the sliding frame 5 and the horizontal arm 6 in the respective directions described above. The movement of the laser unit 10, that is, the sliding movements of the base plate 3, the sliding

frame 5 and the horizontal arm 6 in the respective directions described above, can be performed by a suitable known technique by means of a motor or by a manual operation or the like.

A cable 99 connected to the laser unit 10 is connected to a first signal processing circuit 50 described above. The first signal processing circuit 50 outputs, depending upon a difference of the light receiving position of laser light on the light position detecting element 15, an analog signal corresponding to the distance between the laser unit 10 and the subject 100 for measurement. For the laser unit 10 and the first signal processing circuit 50, for example, a laser displacement gauge (LC-2320) and a controller (LC-2100) manufactured by Keyence Kabushiki Kaisha can be used.

The first signal processing circuit 50 is connected to a personal computer 70. A second signal processing circuit 60 includes a time constant circuit for applying output delaying processing for prevention of chattering to an output signal (for example, a signal of a distance between the laser unit 10 and the subject for measurement) of the first signal processing circuit 50, an inverter circuit and so forth. It is to be noted that the second signal processing circuit 60 can be omitted in accordance with a responding condition, a polarity or the like of the output signal of the first signal processing circuit 50.

The layout machine 1 includes a coordinate detecting apparatus 1A for detecting coordinates of the horizontal arm 6 (in other words, coordinates of the reference point LI), and the output signal thereof is outputted to the personal computer 70. The personal computer 70 automatically collects coordinates of the reference point LI, which are an output signal of the coordinate detecting apparatus 1A at a point in time when the subject 100 for measurement reaches the reference point LI, using the output signal of the second signal processing circuit 60 (or the first signal processing circuit 50), and reproduces, in accordance with the requirements, the shape of a profile of the subject for measurement on a CRT using the collected coordinate information. The automatic collection of coordinates will be hereinafter described.

Figure 13 is a front elevational view of the horizontal arm 6 and the intermediate arm 30, wing arm 20 and laser unit 10 mounted on the horizontal arm 6. A pair of bearings 32 and 34 are securely mounted at the opposite ends of the intermediate arm 30, and a main shaft 31 and an auxiliary shaft 33 are inserted for rotation in the bearings 32 and 34. The main shaft 31 is secured to a shaft 6A mounted for rotation at an end of the horizontal arm 6 while the auxiliary shaft 33 is secured to the wing arm 20.

Accordingly, an end portion is farther than the main shaft 31 and the intermediate shaft 30 can be pivoted in the direction indicated by an arrow mark P around the shaft 6A. An end portion farther than the

intermediate arm 30 can be pivoted in the direction indicated by an arrow mark Q around the main shaft 31. In addition, an end portion farther than the wing arm 20 can be pivoted in the direction indicated by an arrow mark R around the auxiliary shaft 33. The pivotal portions are fixed using a suitable known technique upon measurement of coordinates by the present non-contacting three-dimensional measuring instrument.

Now, as shown in Figure 5, the main shaft 31 and the auxiliary shaft 33 provided on the intermediate arm 30 are mounted such that the angle defined by extension lines of the center axes thereof may be 45 degrees. The needle 302 is installed within the region defined between extension lines of an optic axis Lo of laser light radiated from the light emitting portion and an optic axis Ll of laser light received by the light receiving portion when the detection point is at the reference point Lref.

Since originally the region is a region which is assured as a dead spacing into which no cables or the like are admitted in order that laser light may be irradiated with certainty upon a subject for measurement and laser light reflected from the subject for measurement may be received with certainty, if the needle 302 is provided in the region, then the needle 302 will not be connected to cables or the like.

Meanwhile, the laser unit 10 is mounted on the wing arm 20 such that laser light L irradiated in the direction of an arrow mark from the laser unit 10 may make an angle of 45 degrees with respect to the center axis of the auxiliary shaft 33.

Accordingly, if the horizontal arm 6 is directed in the X direction as shown in Figure 6, then if the center line of the main shaft 31 is directed in the X-axis direction so as to be parallel (imaginary line in Figure 13) to the center line of the horizontal arm 6, the irradiation direction L of laser light irradiated from the laser unit 10 can be made to coincide with any one of the X, Y and Z directions as shown in Figures 10(a) to (c) by changing the pivoting position of the intermediate arm 30 with respect to the main shaft 31 and the pivoting position of the wing arm 20 with respect to the auxiliary shaft 33.

Further, according to the present embodiment, it is also possible to direct the irradiation direction of laser light to a direction other than the directions of the three axes described above by pivoting the intermediate arm 30 in the direction of the arrow mark P (Figure 13) with respect to the shaft 6A.

The laser unit 10 is constructed such that it does not irradiate laser light from a central portion thereof but irradiates laser light from a position near a side face thereof. When a recessed portion 100C is formed on the surface of the subject 100 for measurement as shown in Figure 11(a), it is possible to approach a delay angle of the wall face of the recessed portion 100C to effect detection of the coordinates.

Further, since the mounting means of the laser unit 10 on the wing arm 20 may be by screws as described hereinabove, if the laser unit 10 is mounted on the wing arm 20 with the front side directed backwardly, then even if a recessed portion 100D is formed in the direction opposite to that of Figure 11(a) as shown in Figure 11(b), it is possible to approach the wall face of the recessed portion 100D to effect detection of coordinates at many positions.

It is to be noted that, when the laser unit 10 is mounted reversely, the reference point Lref is not on the crossing point between the main shaft 31 and the auxiliary shaft 33 as shown in Figure 11(b), but if the arm 20 is formed such that it is extended in the direction of the center axis of the main shaft 31 (refer to Figure 11(c)) when the wing arm 20 is in the condition of Figure 11(a), then it is possible to mount the laser unit 10 such that the reference point Lref may be positioned on the crossing point between the main shaft 31 and the auxiliary shaft 33 even if the laser unit 10 is directed with the front side directed backwardly.

Referring back to Figure 13, a cable 99 for a power source supply and data outputting led out from the laser unit 10 extends through the inside of the auxiliary shaft 33 and the inside of the horizontal arm 6, which have a hollow structure. The cable extends out from the rear end of the horizontal arm 6. Since the cable 99 is accommodated in the horizontal arm 6 in this manner, the cable 99 does not interfere with a measuring operation and protection of the cable 99 can be achieved. Further, also the quantity of guides (for example, tapes) for fixation of the cable necessary for bundling outer cables is decreased and the appearance is not deteriorated. It is to be noted that also the intermediate arm 30, the main shaft 31 and so forth may have a hollow structure so that the cable 99 may extend also through the insides of the hollow structures.

The intermediate arm 30, wing arm 20 and laser unit 10 mounted at the end portion of the horizontal arm 6 (Figure 6) must be constructed to be of light weight in order to raise the accuracy in three-dimensional measurement. To this end, the wing arm 20 on which the laser unit 10 is mounted has such a framed construction as shown in Figure 8. A shaft hole 21 in which the auxiliary shaft 33 is to be inserted and a mounting hole 22 for mounting the laser unit 10 therein are perforated at suitable positions of the wing arm 20. Further, recessed portions 23 are perforated at the front and back portions of several linear members forming the framed construction described above in order to achieve reduction of the weight of the wing arm 20 (refer to Figure 9).

Due to such construction, reduction in the weight and high rigidity of the wing arm 20 can be achieved. Further, in order to achieve further reduction of the weight and enhance the accuracy of dimensions, the wing arm 20 is produced, for example, from magne-

sium.

It is to be noted that, while the needle 302 in the embodiment described above is described as being installed within the region (parallel to the optic axes LO and LI) defined between the optic axis LO of laser light radiated from the light emitting portion and the optic axis LI of laser light received by the light receiving portion when the detection point is at the reference point Lref with respect to the laser unit 10, the present invention is not limited to this construction. The needle 302 may be installed in such a manner, for example, as shown in Figure 3 only if it can indicate the crossing point between the optic axes LO and LI.

As is apparent from the foregoing description, according to the present invention, the following effects are achieved:

(1) Since the needle 302 is provided on the laser unit 10 and the positional relationship between the detection point and the laser unit may come to the predetermined relationship when the laser unit 10 is moved so that the end of the needle 302 may indicate the detection point, the desired detection point can be designated rapidly and accurately.

(2) If the needle 302 is secured in a readily removable condition to the laser unit 10, then the needle 302 is removed when it is contacted with a subject for measurement and will not damage the subject for measurement.

(3) If the needle 302 is screwed at a rear end portion thereof in the tapping hole of the supporting portion 301, then positioning of the end portion thereof is very easy.

(4) If the supporting portion 301 in which the needle 302 is screwed and the base plate 303 secured to the laser unit 10 are secured to each other by a magnetic force, then the securing of the needle 302 in a readily removable condition can be achieved with a simple construction.

(5) If the needle 302 is disposed so that laser light may be irradiated at the end portion thereof, then designation of the detection point can be readily performed.

(6) If the needle 302 is a transparent member, then admission of randomly reflected light into the light receiving portion is prevented.

(7) If the end portion of the needle 302 is roughened, then since laser light is reflected at random at the end portion, it can be readily visually observed.

(8) If the needle 302 is installed within the range defined by extension lines of the optic axis of laser light radiated from the light emitting portion and the optic axis of laser light received by the light receiving portion when the detection point and the laser unit 10 are in the predetermined positional relationship, the needle 302 is not contacted with cables or the like.

Figure 15 is a perspective view of an embodiment of the present invention. Referring to Figure 15, a layout machine 1000 is installed on a surface plate 2000, and a guide rail 2002 thereof is secured to the surface plate 2000. A base plate 2003 of the layout machine 1000 is slidably movable in the Y direction along the guide rail 2002 and a sliding frame 2005 is slidably movable in the Z direction along a vertical arm 2004 supported vertically on the base plate 2003. Further, a horizontal arm 2006 is slidably movable in the X direction along the sliding frame 2005. A laser unit 1010 is mounted at an end of the horizontal arm 2006 by way of an intermediate arm (first intermediate arm) 2030 and a wing arm (second intermediate arm) 2020. The wing arm 2020 and the laser unit 1010 may be secured together by screws.

Accordingly, the laser unit 1010 is movable to a suitable location within a three-dimensional spacing above the surface plate 2000 by sliding movements of the base plate 2003, the sliding frame 2005 and the horizontal arm 2006 in the respective directions described above. The movement of the laser unit 1010, that is, the sliding movements of the base plate 2003, the sliding frame 2005 and the horizontal arm 2006 in the respective directions described above, can be performed by a suitable known technique by means of a motor or by a manual operation or the like.

The structure of the laser unit 1010 is shown in Figure 16. A semiconductor laser 1012 is driven by a semiconductor laser driving circuit 1011 to radiate laser light. The laser light is irradiated upon the subject 1100 for measurement by way of a light projecting lens 1013. When the subject 1100 for measurement is disposed at a reference point L, for example, at the distance of 50 mm in the laser light irradiation direction from the laser light irradiation position of the laser unit 1010, laser light reflected at random from the subject 1100 for measurement is received at a central position of a light position detecting element 1015 by way of a light receiving lens 1014. Further, when the subject 1100 for measurement is nearer or farther than the reference point as indicated by reference characters 1100A and 1100B, the light receiving position of laser light on the light position detecting element 1015 moves in the direction of the arrows A or B. The output of the light position detecting element 1015 is outputted to a first signal processing circuit 1050, Figure 15, by way of amplifiers 1016 and 1017.

Referring back to Figure 15, a cable 1099 connected to the amplifiers 1016 and 1017 as well as the semiconductor laser driving circuit 1011 of the laser unit 1010 is connected to the first signal processing circuit 1050 described above. The first signal processing circuit 1050 serves as a power source for the semiconductor laser driving circuit 1011 and has the function of outputting, depending upon a difference of the light receiving position of laser light on the light position detecting element 1015, an analog signal

corresponding to the distance between the laser unit 1010 and the subject 1100 for measurement. When the distance between the laser unit 1010 and the subject 1100 becomes smaller or larger than a preset distance, a digital signal is outputted representing the distance. A laser displacement gauge LC2320 and a controller LC-2100 manufactured by Keyence Kabushiki Kaisha can be used, for example, for the laser unit 1010 and the first signal processing circuit 1050.

The first signal processing circuit 1050 is connected to a personal computer 1070 by way of a second signal processing circuit 1060. The second signal processing circuit 1060 includes a time constant circuit for applying output delaying processing for prevention of chattering to an output signal, for example, a signal of a distance between the laser unit 1010 and the subject for measurement, of the first signal processing circuit 1050, an inverter circuit and so forth. It is to be noted that the second signal processing circuit 1060 can be omitted in accordance with a responding condition, a polarity or the like of the output signal of the first signal processing circuit 1050.

The layout machine 1000 includes a coordinate detecting apparatus 1001A for detecting coordinates of the horizontal arm 2006, in other words, coordinates of the reference point L1, and the output signal thereof is outputted to the personal computer 1070. The personal computer 1070 automatically collects coordinates of the reference point L1, which are an output signal of the coordinate detecting apparatus 1001A at a point in time when the subject 1100 for measurement reaches the reference point L, using the output signal of the second signal processing circuit 1060, or the first signal processing circuit 1050, and reproduces as in accordance with the necessity, the shape of a profile of the subject for measurement on a CRT using the fetched coordinate information. The automatic collection of coordinates will be hereinafter described.

Laser light protective goggles 1090 are provided to protect the eyes of a measuring person from laser light irradiated from the laser unit 1010, and blue and red LEDs 1091 and 1092 are mounted at an upper portion of the laser light protective goggles 1090 so that they may be included in the field of view of the measuring person. An enlarged view of the laser light protective goggles 1090 is shown in Figure 29. The blue LED 1091 and the red LED 1092 are connected to the second signal processing circuit 1060, or the first signal processing circuit 1050. Also the manner of use of the blue LED 1091 and the red LED 1092 will be hereinafter described.

A subject for measurement (not shown) is placed on the surface plate 2000, and also a reference cube 1080 is mounted on a frame 1300 which is placed on the surface plate 2000. Also the construction and the manner of use of the reference cube 1080 will be hereinafter described.

Figure 17 is a front elevational view of the horizontal arm 2006 and the intermediate arm 2030, wing arm 2020 and laser unit 1010 mounted on the horizontal arm 2006, all shown in Figure 15. In Figure 17 like reference numerals to those of Figure 15 denote like or equivalent portions. First, a pair of bearings 2032 and 2034 are securely mounted at the opposite ends of the intermediate arm 2030, and a main shaft 2031 and an auxiliary shaft 2033 are inserted for rotation in the bearings 2032 and 2034. The main shaft 2031 is secured to a shaft 2006A mounted for rotation at an end of the horizontal arm 2006 while the auxiliary shaft 2033 is secured to the wing arm 2020. Accordingly, an end portion farther than the main shaft 2031 and the intermediate shaft 2030 can be pivoted in the direction indicated by an arrow P around the shaft 2006A. An end portion farther than the intermediate arm 2030 can be pivoted in the direction indicated by an arrow Q around the main shaft 2031. An end portion farther than the wing arm 2020 can be pivoted in the direction indicated by an arrow R around the auxiliary shaft 2034. The pivotal portions are fixed using a suitable known technique upon measurement of coordinates by the present non-contacting three-dimensional measuring instrument.

Now, as shown in Figure 14, the main shaft 2031 and the auxiliary shaft 2033 provided on the intermediate arm 2030 are mounted such that the angle defined by extension lines of the center axes thereof may be 45 degrees. Meanwhile, the laser unit 1010 is mounted on the wing arm 2020 such that laser light irradiated in the direction of an arrow mark L from the laser unit 1010 may make an angle of 45 degrees with respect to the center axis of the auxiliary shaft 2033.

If the horizontal arm 2006 is directed in the X direction as shown in Figure 15, then if the center line of the main shaft 2031 is directed in the X axis direction so as to be parallel (imaginary line in Figure 17) to the center line of the horizontal arm 2006, the irradiation direction L of laser light irradiated from the laser unit 1010 can be made to coincide with any one of the X, Y and Z directions as shown in Figures 10(a) to 10(c) by changing the pivoting position of the intermediate arm 2030 with respect to the main shaft 2031 and the pivoting position of the wing arm 2020 with respect to the auxiliary shaft 2033.

In the embodiment of the present invention, when laser light is irradiated in the X direction as shown in Figures 18(a) and 18(b), the distance to the subject 1100 for measurement can be adjusted by feeding the laser unit 1010 only in the same direction without varying the irradiation position of the laser light. Accordingly, detection of coordinates of an outer profile of the subject 1100 for measurement by the non-contacting three-dimensional measuring instrument can be performed readily. While, naturally with such a coordinate detecting method, laser light cannot be irradiated perpendicularly upon a position of the subject

1100 for measurement for which coordinates are to be detected, since the coordinate detecting method is of the non-contacting type employing laser light, no deterioration of the accuracy in detection of the coordinate position occurs.

Further, it is also possible to direct the irradiation direction of laser light to a direction other than the directions of the three axes described above by pivoting the intermediate arm 2030 in the direction of the arrow mark P (Figure 17) with respect to the shaft 2006A.

Further, since the laser unit 1010 is constructed such that it does not irradiate laser light from a central portion thereof but irradiates laser light from a position near a side face thereof, also when a recessed portion 100C is formed on the surface of the subject 100 for measurement as shown in Figure 11(a), it is possible to approach a delay angle of the wall face of the recessed portion 100C to effect detection of coordinates. Further, since the mounting means of the laser unit 1010 on the wing arm 2020 is screws as described hereinabove, if the laser unit 1010 is mounted on the wing arm 2020 with the front side directed backwardly, then even if a recessed portion 100D is formed in the direction opposite to that of Figure 11(a) as shown in Figure 11(b), it is possible to approach the wall face of the recessed portion 100D to effect detection of coordinates at many positions.

It is to be noted that, when the laser unit 1010 is mounted reversely, the reference point LI is not on the crossing point between the main shaft 2031 and the auxiliary shaft 2033 as shown in Figure 11(b), but if the arm 2020 is formed such that it extends in the direction of the center axis of the main shaft 2031 (refer to Figure 11(c)) when the wing arm 2020 is in the condition of Figure 11(a), then it is possible to mount the laser unit 1010 such that the reference point LI may be positioned on the crossing point between the main shaft 2031 and the auxiliary shaft 2033 even if the laser unit 1010 is directed with the front side directed backwardly.

In this manner, in the present embodiment, measurement of the inside of a recessed portion can be performed readily and with a high degree of accuracy. In other words, interference is small and the measurement limit is high.

Further, in the present embodiment, since the laser unit 1010 is mounted on the wing arm 2020 such that the reference point LI is positioned at the crossing point between the center axes of the main shaft 2031 and the auxiliary shaft 2033 as shown in Figures 14 and 17, even if, for example, the wing arm 2020 and/or the intermediate arm 2030 are pivoted to vary the irradiation direction of laser light as shown in the several views of Figures 10(a) to 10(c), the position of the reference point LI does not vary.

Accordingly, even if any of the arms 2020 and 2030 is pivoted, there is no need of adjusting the ori-

gin of the layout machine 1000 very thin.

Referring back to Figure 17, a cable 1099 for power source supply and data outputting led out from the laser unit 1010 extends through the inside of the auxiliary shaft 2033 and the inside of the horizontal arm 2006, which have a hollow structure, and extends out from the rear end of the horizontal arm 2006. Since the cable 1099 is accommodated in the horizontal arm 2006 in this manner, the cable 1099 does not interfere with a measuring operation and protection of the cable 1099 can be achieved. Further, also the quantity of guides (for example, tapes) for fixation of the cable necessary for bundling outer cables is decreased and the appearance is not deteriorated. It is to be noted that also the intermediate arm 2030, the main shaft 2031 and so forth may have a hollow structure so that the cable 1099 may extend also through the insides of the shafts.

The intermediate arm 2030, wing arm 2020 and laser unit 1010 mounted at the end portion of the horizontal arm 2006 (Figure 15) must be constructed to be light in weight in order to increase the accuracy in three-dimensional measurement. To this end, the wing arm 2020 on which the laser unit 1010 is mounted has a frame construction as shown in Figure 8, as previously described.

The intermediate arm 2030 on which the wing arm 2020 is mounted is produced by winding carbon fibers on an outer periphery of an epoxy honeycomb, which is to make a core member, and securely mounting the bearings 2032 and 2034 onto the opposite ends of the epoxy honeycomb using a jig. In the following, the structure and the manufacturing process of the intermediate arm 2030 will be described with reference to Figures 20(a), 20(b), 21(a), 21(b), 22, 23, 24, 25 and 26. It is to be noted that hatching lines are omitted in Figures 20(b), 21(b) and 22.

First, as shown in Figures 20(a) and 20(b), a pair of epoxy honeycombs 3035, 3036 which are to make a core member of the intermediate arm 2030 and construct part of an annular shape are adhered in an opposing relationship to each other. Then, carbon fibers 3037 are adhered to the surface of the epoxy honeycomb 3035 as shown in Figures 21(a) and 21(b), and carbon fibers 3037 are adhered also to the surface of the epoxy honeycomb 3036. The adhesion is performed, for example, by disposing the carbon fibers 3037 in advance in a female die having a profile shape similar to that of the epoxy honeycomb 3035 or 3036 and inserting the epoxy honeycomb 2035 or 3036 into the female die. It is to be noted that the adhesion of the carbon fibers 3037 may be performed before the epoxy honeycombs 3035 and 3036 are adhered to each other. Thereafter, carbon fibers 3038 are wound once more on and adhered to the carbon fibers 3037.

It is to be noted that, since the carbon fibers are longer than the epoxy honeycombs 3035 and 3036,

recessed portions 3039 for mounting the bearings 3032 and 3034, which will be hereinafter described, are formed at the opposite ends of the epoxy honeycombs 3035 and 3036 as a result of adhesion of the carbon fibers.

After the adhesion of the carbon fibers is completed in this manner, the bearings (slide bearing) 3032 and 3034 made of, for example, aluminium are mounted using such a jig apparatus 3110 as shown in Figure 23. Referring to Figure 23, first, a column portion 3112B is formed on a first mounting jig 3112 such that a mounting face 3112A perpendicular to the center axis of the first mounting jig 3112 may be formed, and a male screw 3112C is formed at an end of the column portion 3112B. Further, another male screw 3112D is formed on the opposite side to the male screw 3112C, and the first mounting jig 3112 is mounted on a jig plate 3111 by screwing a nut 3115 on the male screw 3112D.

A second mounting jig 3113 is mounted on the jig plate 3111 such that a mounting face 3113A thereof makes an angle of 45 degrees with respect to the mounting face 3112A. Further, a hole portion 3113B is perforated perpendicularly to the mounting face 3113A in the mounting face 3113A.

A third mounting jig 3114 is constituted from a column portion 3114A, a leg portion 3114B having a smaller diameter than the column portion 3114A and a male screw 3114C formed at an end of the leg portion 3114B. In Figure 23, the third mounting jig 3114 is mounted on the second mounting jig 3113 by inserting the leg portion 3114B in the hole portion 3113B and screwing the male screw 3114C in the nut 3116, but before positioning of the intermediate arm 2030, the third mounting jig 3114 is in a removed condition.

In order to produce the intermediate arm 2030 using such a jig apparatus 3110, first, the bearing 3032 is fitted onto the column portion 3112B of the jig apparatus 3110 as shown in Figure 24, and after the insertion, the nut 3118 is screwed onto the male screw 3112C with a washer 3117 interposed therebetween to secure the bearing 3032 in a condition wherein the bearing 3032 is closely contacted with the mounting face 3112A.

Subsequently, a protruded portion 3034A of the bearing 3034 is inserted as shown in Figure 25 into one of the recessed portions 3039 of the epoxy honeycombs 3035 and 3036 around which carbon fibers are wound as described hereinabove with reference to Figs. 20(a), 20(b), 21(a), 21(b) and 22, and in this condition, the bearing 3034 is secured to the mounting face 3113A so that a protruded portion 3032A of the bearing 3032 secured to the first mounting jig 3112 may be inserted into the other recessed portion 3039 as shown in Figure 26. The securing is performed by inserting the column portion 3114A of the third mounting jig 3114 into the bearing 3034 as shown in Figure 26. Thereafter, the leg portion 3114B

data at the minus side distance measurement limit position are collected. As a result, a signal having an error of about 9 mm is inputted, and accordingly, in order to prevent such a situation, the red LED 1092 is illuminated at a point in time when the subject 1100 for measurement approaches nearer than the reference point L so as to give a warning to an operator of the, non-contacting three-dimensional measuring instrument. In particular, when the red LED 1092 is lit, if the layout machine 1000 (Figure 15) is operated immediately so that the laser unit 1010 may be moved away, then double detection of coordinate data can be prevented.

It is to be noted that, if the first signal processing circuit 1050 has a function that, even if the distance between the laser unit 1010 and the subject 1100 for measurement becomes smaller or greater than the preset difference, a digital signal indicating this is not outputted immediately but a signal is outputted when the distance described above still continues even after lapse of about 1 second, then if the function is applied to the case wherein the subject 1100 for measurement enters in the minus direction farther than the minus side distance measurement limit position, then even if the laser unit 1010 approaches the subject 1100 for measurement excessively until the red LED 1092 is extinguished momentarily, double detection of coordinate data can be prevented by moving the laser unit 1010 away from the subject 1100 for measurement before lapse of about 1 second.

Figure 31 is a functional block diagram of an embodiment of the present invention. Referring to Figure 31, like reference characters to those of Figure 15 denote like or equivalent portions. A distance signal which is output data of the laser unit 1010 is inputted to the blue light region judging means 3301 and red light region judging means 3302. The blue light region judging means 3301 judges whether or not the position of the subject for measurement is positioned within the range from the position of 1 mm from the reference point to the plus side distance measurement limit position, and in the case of an affirmative judgment, the blue LED 1091 is energized and illuminated. Meanwhile, the red light region judging means 3302 judges whether or not the subject for measurement is positioned within the range from the position of about -3 mm from the reference point to the minus side distance measurement limit position, and in the case of an affirmative judgment, the red LED 1092 is energized and illuminated.

An inverter 3305 generates an output when the subject for measurement approaches nearer than the reference point. A gate 3307 is triggered by an output of the inverter 3305, whereupon it outputs coordinate data (X, Y and Z coordinate data) outputted from the coordinate detecting means 3308 (coordinate detecting apparatus 1001A) to coordinate storage means 3309. Image reproducing means 3310 reproduces,

using coordinate data stored in the coordinate storage means 3309, a profile of the same using a suitable known technique. As a result, an output to display means 3311, on which it is displayed is generated. The gate 3307, coordinate storage means 3309, image reproducing means 3310 and display means 3311 are functions of the personal computer 1070 (Figure 15).

With the construction described above, while the laser unit 1010 must be moved away from the subject for measurement immediately when the red LED 1092 is illuminated, double detection of coordinate data can be prevented by executing such processing as illustrated in Figure 32. The processing is executed, for example, by the personal computer 1070.

Referring to Figure 32, first at step S1, a flag F is reset to "0". At step S2, distance data D which is output data (data of the distance to the subject for measurement) of the laser unit 1010 is inputted. At step S3, it is judged whether or not D is within the range from the distance of 1 mm from the reference point to the plus side distance measurement limit. In the case of an affirmative judgment, the blue LED 1091 is illuminated at step S4, but in the case of a negative judgment, the blue LED 1091 is extinguished at step S5.

At step S6, it is judged whether or not D is within the range from the distance of -3 mm from the reference point to the minus side distance measurement limit. In the case of the affirmative judgment, the red LED 1092 is illuminated at step S7, but in the case of the negative judgment, the red LED 1092 is extinguished at step S8.

At step S9, it is judged whether or not D has a positive value, that is, whether or not D is within the range from 0 mm to the plus side distance measurement limit. In the case of an affirmative judgment, the flag F is set to "1" at step S10.

At step S11, it is judged whether or not the flag F is "1", and if the flag F is "1", it is judged at step S12 whether or not D has become minus. If D is minus data, then coordinate data of the reference point L are fetched at step S13, and then at step S14, the flag F is reset to "0". Thereafter, the processing returns to step S2. If a negative judgment is made at step S11 or S22 described above, then the processing returns to step S2.

A functional block diagram of another embodiment of the present invention which executes such processing is illustrated in Figure 33. Referring to Figure 33, like reference numerals to those of Figure 31 denote like or equivalent portions, and accordingly, description thereof is omitted herein. A positive region judging means 3303 judges, using output data of the laser unit 1010 whether or not the position of the subject for measurement is within the range from the reference point to the plus side distance measurement limit. In the case of an affirmative judgment, the positive region judging means 3303 energizes flag gen-

erating means 3304 to set the flag F to "1" (generate a flag). An AND gate 3306 is opened by the generation of a flag.

An inverter 3305 generates an output when the subject-for measurement approaches nearer than the reference point. Accordingly, when the subject for measurement approaches nearer than the reference point after generation of a flag, an output is generated from the AND gate 3306 so that a gate 3307 is opened, and consequently, coordinate data outputted from the coordinate detecting means 3308 are outputted to coordinate storage means 3309. The coordinate storage means 3309 deenergizes, after the coordinate data have been stored, the flag generating means 3304 to stop generation of a flag.

In this manner, in the present example, since double detection of coordinate data by excessive approach to the subject for measurement is prevented, lighting of the red LED 1092 need not particularly be performed. Further, while it is described that the blue LED 1091 and the red LED 1092 are provided on the laser light protective goggles 1090, the blue LED 1091 and the red LED 1092 may be disposed at any position only if the blue LED 1091 and the red LED 1092 can be visually observed simultaneously while laser light irradiated from the laser unit 10 upon the subject for measurement is watched. In particular, they may be provided, for example, in the proximity of the subject for measurement.

While position control of the laser unit 1010 can be performed simply if the measuring person visually observes an illuminated condition wherein the blue LED 1091 and the red LED 1092 are illuminated, the measuring person must always visually observe laser light irradiated from both the laser unit 1010 upon the subject for measurement and the blue LED 1091 and the red LED 1092.

On the other hand, in the example described below, position control of the laser unit 1010 can be performed simply only by visual observation only of a portion in the proximity of a coordinate measurement position of the subject for measurement. Figure 34 is a schematic view showing another example of a laser unit. Referring to Figure 34, like reference characters to those of Figure 16 denote like or equivalent portions. As is apparent from Figure 34, an auxiliary light source apparatus 1018 is provided in the present laser unit 1010A. The auxiliary light source apparatus 1018 includes an auxiliary light source (for example a high brightness LED) 1018A, a light introducing fiber 1018B and a lens 1018C. The lens 1018C is mounted such that it does not interfere with a route of laser light incoming to the light position detecting element 1015, and is constructed and mounted such that it converts light S radiated from the auxiliary light source 1018A into substantially parallel light similar to the laser light L irradiated from the semiconductor laser 1012 and the light S is irradiated upon the reference point LJ.

A positional relationship between the laser unit 1010A and the subject 1100 for measurement when the laser unit 1010A is moved toward the subject 1100 for measurement and a relationship between spots of laser light and auxiliary light irradiated upon the subject 1100 for measurement are illustrated in Figures 35(a), 35(b) and 35(c). It is to be noted that the diameters of the spots of laser light and auxiliary light irradiated upon the subject 1100 for measurement are, for example, 0.4 mm and 4 mm, respectively.

First, when the reference point LJ is spaced far away from the surface of the object 1100 for measurement as shown in Figure 35(a), the spot SP of auxiliary light is at a position different from that of the spot LP of laser light. If the laser unit 1010A is gradually moved from its position, toward the subject 1100 for measurement, then the spot SP approaches the spot LP.

When the reference point LJ reaches the surface of the subject 1100 for measurement, the spot SP of auxiliary light moves to (that is, becomes concentric with) the spot LP so that the center thereof may coincide with the center of the spot LP of laser light as shown in Figure 35(b). If the laser unit 1010A is moved further from the condition toward the subject 1100 for measurement, then the spot SP moves to the opposite side to that of Figure 35(a) as shown in Figure 35(c).

In this manner, if the laser unit 1010A provided with the auxiliary light source 1018 is used, then measurement of coordinates of the subject 1100 for measurement can be performed readily without provision of the blue LED 1091 and the red LED 1092 on the laser light protective goggles 1090. Naturally, in such a measuring method, the position judging method of a laser unit using the blue LED 1091 and the red LED 1092 may be additionally provided.

When the irradiation angle of auxiliary light S with respect to the subject 1100 for measurement is decreased so that the auxiliary light source apparatus 1018 comes to a condition in which it is just before contacting with the subject 1100 for measurement (hereinafter referred to as "interference") as shown in Figure 38; it is impossible to move the laser unit 1010A any further to the subject 1100 for measurement to effect detection of coordinates. However, if the auxiliary light source apparatus 1018 is made foldable so as to decrease the amount of projection of the auxiliary light source apparatus 1018 from the laser unit 1010A, then it is possible to cause the laser unit 1010A to further approach the subject 1100 for measurement. Naturally, in this instance, positioning by using auxiliary light is not performed.

Figures 39(a), 39(b), 40(a) and 40(b) are views showing a laser unit 1010A provided with a foldable auxiliary light source apparatus 1018. Figure 39(a) is a view illustrating a condition wherein the auxiliary light source apparatus 1018 is erected uprightly to ir-

radiate auxiliary light S upon the reference point L1, Figure 39 (b) is a bottom plan view of Figure 39 (a). Figure 40 (a) is a view illustrating a condition wherein the auxiliary light source apparatus 1018 is folded, and Figure 40 (b) is a bottom plan view of Figure 40 (a).

As apparent from Figures 39(a), 39(b), 40(a) and 40(b), a frame 1018D is securely mounted on a casing of the laser unit 1010A and an arm 1018E on which a lens 1018C for irradiation of auxiliary light S is mounted for pivotal motion on the frame 1018D. The frame 1018D supports the arm 1018E for pivotal motion thereon so that the arm 1018E may be pivoted within a plane different from the plane which includes the irradiation direction L of laser light and the reflection direction of the laser light.

Accordingly, upon interference of the auxiliary light source apparatus 1018, if the arm 1018E is pivoted to the laser unit 1010A side, then the amount of projection of the auxiliary light source apparatus 1018 from the laser unit 1010A can be reduced without interfering with the route of laser light and it is possible to cause the laser unit 1010A to further approach the subject for measurement to effect detection of coordinates.

It is to be noted that, while, in the description regarding Figure 34, the auxiliary light source 1018A is disposed in the inside of the laser unit 1010A, it is a matter of course that the auxiliary light source 1018A may be mounted outside the laser unit 1010A.

If all coordinates of the subject for measurement can be measured without changing the mounting position of the laser unit 1010 on the horizontal arm 2006 (Figure 15) at all, then a profile shape of the subject for measurement can be recognized only from a relative positional relationship of the coordinates of the points on the subject for measurement, but since the subject for measurement has a three-dimensional shape, if laser light is irradiated in a certain direction upon the subject for measurement to measure coordinates, for example, on the front surface side of the subject for measurement, then the irradiation direction of the laser light must be changed, for example, to the opposite direction to measure coordinates on the rear surface side of the subject for measurement. When it is attempted to perform measurement of coordinates of the subject for measurement with a higher degree of accuracy, the irradiation direction of laser light must necessarily be changed three or more times.

Here, if the laser unit 1010 is mounted on the wing arm 2020 such that the reference point L1 may be positioned on the crossing point between the center axes of the main shaft 2031 and the auxiliary shaft 2033 as described hereinabove with reference to Figure 14, then the position of the reference point L1 is not varied even if the wing arm 2020 and/or the intermediate arm 2030 are pivoted to change the irradiation

direction of laser light. Accordingly, even if the arms 2020 and 2030 are pivoted, adjustment of the origin of the layout machine 1000 need not be performed every time.

However, when the arms 2020 and 2030 do not have the construction as described above, if the mounting position of the laser unit 1010 is changed, then the position of the reference point L1 is displaced by the change, and accordingly, it has been a conventional practice to perform such origin adjustment as described below each time the mounting position of the laser unit 1010 is changed.

In particular, the origin adjustment is performed by making, before measurement of coordinates by the three-dimensional measuring instrument, the reference point of the laser unit coincide with the point marked at a predetermined position of the subject for measurement and setting coordinates (X, Y and Z coordinates) outputted from the layout machine then as the origin. Then, the origin adjustment must be performed each time the mounting position of the laser unit 1010 on the layout machine 1000 is changed.

According to the origin adjustment, if the reference point L1 in the radiation direction of laser light is made to coincide with a marked point which makes an aim, then the X, Y and Z coordinates of the reference point L1 are determined simultaneously. Here, even when the position of the reference point L1 is changed by variation of the irradiation direction of laser light, it is easy to make the reference point coincide with a predetermined point as described hereinabove with reference to Figures 14 to 17 if the laser light irradiation direction is directed in the direction of any one of the X, Y and Z axes, and accordingly, also origin adjustment is easy.

However, when the laser light irradiation direction is not directed to any of the X, Y and Z axis directions, in order to make the reference point L1 coincide with the marked point, the laser unit must necessarily be moved simultaneously in the directions of the three axes, and accordingly, positioning thereof is cumbersome. Further, with a non-contacting three-dimensional measuring instrument employing laser light, since detection of coordinates can be performed with a high degree of accuracy, also the positioning described above must be performed accurately, which is cumbersome.

Further, when the subject for measurement is formed from clay and a mark is applied by marking-off to the surface of the subject for measurement, since concave and convex are formed at the marked-off portions, accurate origin adjustment is difficult.

In the following, an origin adjusting method will be described wherein the X, Y and Z coordinates of the origin are successively determined, in a three-dimensional measuring instrument which has such a construction that the position of the reference point L1 is displaced when the irradiation direction of laser

light is changed, by adjusting the reference point not to a point but to a predetermined plane in order to solve such a disadvantage as described above. It is to be noted that the present origin adjusting method can be applied to the case wherein the irradiation direction L of laser light irradiated from the laser unit 1010 does not coincide with any one of the X, Y and Z directions as shown in Figures 10(a) to 10(c). Accordingly, a portion of an arm (the wing arm 2020 and the intermediate arm 2030) which interconnects the horizontal arm 2006 (Figure 15) and the laser unit 1010 need not have such a construction as shown in Figure 14.

Figure 36 is a perspective view of a reference cube 1080 for use with the origin adjusting method described above. Referring to Figure 36, a support bar 1083 is implanted on a frame 1082, and a cube 1081 is placed on the support bar 1083. The cube 1081 is a parallelepiped, wherein the flatness, the parallelism and the perpendicularity of and between the five faces thereof except the lower face are accurately set. Further, the upper face of the cube 1081 is set in parallel to the bottom face of the frame 1082. The reference cube 1080 is placed on a surface plate 2000 as shown in Figure 15. It is to be noted that the support bar 1083 described above is provided when the layout machine 1000 cannot be lower than the reference point of the laser unit 1010 by very much. Accordingly, when the reference point can be lowered to a position in the proximity of the surface plate 2000, in particular, even when the cube 1081 is placed directly on the surface plate 2000, if the reference point LI can be moved with respect to the five faces of the cube 1081 except the bottom face, then the support bar 1083 and the frame 1082 are unnecessary.

Figure 37 is a flow chart illustrating an origin adjusting technique using the reference cube 1080 and a technique of measuring coordinates of a subject for measurement using the technique. First, at step S51 the reference cube 1080 is positioned accurately with respect to a coordinate system defined by the layout machine 1000 (Figure 15). Particularly, the placement of the reference cube 1080 on the surface plate 2000 is performed at a position at which it does not interfere with measurement of coordinates of a subject for measurement (not shown) so that the five faces of the cube 1081 except the lower face may be individually parallel to the X-Y plane, the X-Z plane and the Y-Z plane defined by the layout machine 1000 (Figure 15). One of the eight corners, points, of the cube 1081 makes the origin.

At step S52, the positional relationship between a point (hereinafter referred to as "marked point") marked in advance on the subject for measurement by marking-off or the like and the origin is measured by a suitable method.

At step S53, angle adjustment of the laser unit 1010 is performed so that the laser light irradiation di-

rection L may be directed in a direction other than the directions of the X, Y and Z axes. By such a setting, it is possible to irradiate laser light upon three adjacent faces (the X-Y plane, the X-Z plane and the Y-Z plane) of the reference cube 1080 except the lower face.

At step S54, laser light is irradiated upon the X-Y plane to adjust the reference point LI to the plane. And at step S55, a Z coordinate outputted from the layout machine 1000 then is fetched. Similarly, at steps S56 and S57 as well as S58 and S59, the reference point LI is adjusted to the X-Z plane and the Y-Z plane, and a Y coordinate and an X coordinate outputted from the layout machine 1000 then are collected. Coordinates of the origin are determined using the X, Y and Z coordinates obtained by the processing at those steps S54 to S59 as well as, where necessary, lengths of the sides of the cubes 1081.

At step S60, measurement of coordinates of the subject for measurement are executed. Coordinates thus measured are modified using the coordinates of the origin detected at steps S54 to S59. At step S61, it is judged whether or not it is necessary to perform adjustment of the angle of the laser unit 1010. If the angle adjustment is necessary, the processing returns to step S53. However, if there is no necessity of angle adjustment, then the processing comes to an end.

Since coordinates of the origin can be detected only by adjusting the reference point LI of laser light to three adjacent faces of the reference cube 1080, even when the laser light irradiation direction is not directed in any of the coordinate axes, adjustment of the origin is easy. In particular, since only the reference point LI is made to coincide with one face of the cube 1081, even if laser light is not directed to any of the directions of the three axes, it is possible to position the reference point LI to an aimed face by moving the laser unit 1010 in one of the directions of the coordinate-axes. Accordingly, the adjustment of the origin can be performed readily compared with the conventional technique wherein the reference point is made to coincide with a marked point.

It is to be noted that the processing at step S52 described above can be omitted. Further, while it is described that the five faces of the cube 1081 except the lower face are used, if laser light can be radiated upwardly, then coordinates of the origin can naturally be determined using the bottom face of the cube 1081.

With the non-contacting three-dimensional measuring instrument according to the present invention, since the laser light irradiation direction can be directed to all of the directions of the three axes constituting the coordinate system, if laser light is irradiated in advance upon a desired position of a subject for measurement, then the reference point can be moved to the desired position only by moving the las-

er unit in the laser light irradiation direction. Accordingly, detection of coordinates of the aimed position of the subject for measurement can be performed readily.

With the non-contacting three-dimensional measuring instrument according to the present invention, since the position of the reference point need not be varied even if the irradiation direction of laser light is varied, adjustment of the origin need not be performed each time the irradiation direction is varied. Accordingly, measurement of coordinates by the non-contacting three-dimensional measuring instrument is easy.

With the non-contacting three-dimensional measuring instrument according to the present invention, since measurement of coordinates can be performed in the proximity of a wall face of a recessed portion of the surface of the subject for measurement, measurement of the inside of the recessed portion can be performed readily and with a high degree of accuracy. In other words, interference is small even at a recessed portion and the range in which measurement can be performed is wide.

With the non-contacting three-dimensional measuring instrument according to the present invention, since the first intermediate arm can be constructed light in weight and strong, the structure of a layout machine on which the first intermediate arm, the laser unit and other members are mounted need not be made specifically strong. The non-contacting three-dimensional measuring apparatus can be constructed using a ready made layout machine as is applied to a contacting three-dimensional measuring instrument which employs a needle.

The invention being thus described, it will be obvious that the same may be varied in many ways. Such variations are not to be regarded as a departure from the scope of the invention, and all such modifications as would be obvious to one skilled in the art are intended to be included within the scope of the following claims.

## Claims

1. A non-contacting position detecting apparatus comprising:

a laser unit having a light emitting portion and a light receiving portion for irradiating laser light upon a detection point of a subject for measurement and receiving laser light reflected from the detection point to recognize the distance to the detection point;

an arm capable of moving said laser unit in the direction of at least one axis of a rectangular coordinate system; and

coordinate detecting means for detecting coordinates of said arm, and wherein coordinates

of the detection point are recognized in accordance with the coordinates of said arm when the positional relationship between the detection point and said laser unit reaches a predetermined relationship; wherein

said laser unit includes needle-like indicating means for indicating the crossing point between extension lines of an optic axis of laser light radiated from said light emitting portion and an optic axis of laser light received by said light receiving portion when the detection point and said laser unit reach the predetermined positional relationship.

2. A non-contacting position detecting apparatus according to claim 1, wherein said needle-like indicating means is readily, removably secured to said laser unit.
3. A non-contacting position detecting apparatus according to claim 1 or 2, wherein said needle-like indicating means includes a base plate secured to said laser unit, a supporting portion having a tapping hole and secured to said base plate with a comparatively weak holding force, and a needle screwed in said tapping hole of said supporting portion.
4. A non-contacting position detecting apparatus according to claim 3, wherein said base plate and said supporting portion are secured to each other by a magnetic force.
5. A non-contacting position detecting apparatus according to any preceding claim, wherein said needle-like indicating means is disposed so that laser light may be irradiated at an end portion thereof.
6. A non-contacting position detecting apparatus according to any preceding claim, wherein said needle-like indicating means is constructed from a transparent material.
7. A non-contacting position detecting apparatus according to any preceding claim, wherein an end portion of said needle-like indicating means has a roughened surface.
8. A non-contacting position detecting apparatus according to any preceding claim, wherein said needle-like indicating means is installed within a region defined between the extension lines of the optic axis of laser light radiated from said light emitting portion and the optic axis of laser light received by said light receiving portion when the detection point and said laser unit are in the predetermined positional relationship.

9. A non-contacting three-dimensional measuring instrument which includes an arm movable in the directions of axes of coordinates of a rectangular coordinate system, a laser unit mounted- at an end of said arm for detecting the distance to a subject for measurement, and coordinate detecting means for detecting coordinates of said arm, comprising:
- a main shaft provided on said arm such that the direction of the center axis thereof is directed in the direction of one of the axes of coordinates;
  - a first intermediate arm provided for pivotal motion on said main shaft;
  - an auxiliary shaft provided on said first intermediate arm such that it makes an angle of 45 degrees with respect to said main shaft;
  - a second intermediate arm provided for pivotal motion on said auxiliary shaft; and
  - laser unit mounting means for mounting said laser unit on said second intermediate arm such that the direction of laser light irradiated from said laser unit makes an angle of approximately 45 degrees with respect to said auxiliary shaft.
10. A non-contacting three-dimensional measuring instrument according to claim 9, wherein said laser unit mounting means mounts said laser unit on said second intermediate arm such that the reference point at a predetermined distance in the laser light irradiation direction may be positioned at the crossing point between said main shaft and said auxiliary shaft.
11. A non-contacting three-dimensional measuring instrument according to claim 9 or 10, wherein said laser unit is constructed so as to irradiate laser light from a position other than a central portion thereof, and that said laser unit mounting means can mount said laser unit reversely with regard to the front and rear sides.
12. A non-contacting three-dimensional measuring instrument according to claim 9, 10 or 11, wherein said first, intermediate arm includes a core member made of an epoxy honeycomb, a pair of bearings disposed at the opposite ends of said core member, and carbon fibers wound on the surfaces of said core member and said bearings.
